The In-induced surface reconstruction of the Si(553)-Au surface has been studied using the combined experiment of low-energy-electron diffraction, scanning tunneling microscopy, and angle-resolved photoemission spectroscopy. Low-energy-electron diffraction revealed that In adsorbs interact actively with the surface above 150 °C, widening the terraces uniformly and forming a new atomic wire array. This wire structure has a ×2 period along the wires, where the phase coherence across the wires was much better than that of the pristine Si(553)-Au surface. The In-induced uniform terrace widening was confirmed by scanning tunneling microscopy. More interestingly, the In adsorbates alter the metallic atomic wires of the Si(553)-Au surface with highly dispersive one-dimensional bands into insulating ones with still large dispersion.

One-dimensional (1D) electronic systems have attracted considerable interest on account of exotic phenomena such as Peierls instability and Tomonaga-Luttinger liquid. In order to investigate such 1D phenomena in a real system, electrons need to be delocalized along only a specific direction. This is observed as highly dispersive 1D energy bands in angle-resolved photoemission spectroscopy. There have been few 1D structures with highly dispersive 1D bands because it is not guaranteed that all 1D structures have sufficient electron delocalization.

Recently, few 1D structures with highly dispersive bands were observed on Si surfaces: the In/Si(111)-4×1 surface and the Au/Si(111)-5×2 surface. The three 1D metallic bands of the In/Si(111)-4×1 surface are related to interesting phenomena such as 1D charge density wave (CDW) formation, interband interactions within multiple metallic bands, and the coexistence of metallic and CDW phases. The Au/Si(111)-5×2 surface with 1D bands was reported to show a continuous transition in dimensionality as well as a local electronic structure of a disordered 1D metallic system.

More recently, stepped Si surfaces have been used to provide various 1D structures. The Au adsorption on stepped Si surfaces, Si(557)-Au and Si(553)-Au, were found to produce multiple 1D metallic bands, where the number and band fillings of the 1D bands depend on the substrates. These systems have exhibited interesting phenomena such as the Peierls instability on the Si(557)-Au surface, the coexistence of ×2 and ×3 Peierls distortions within a single unit wire on the Si(553)-Au surface, and spin-orbit-split 1D metallic bands.

In this work, we have attempted to modify the electronic and atomic structures of atomic wires by adsorbing metal atoms in order to provide another degree of freedom in fabricating atomic wires. Indium atoms were deposited on the metallic atomic wires on the Si(553)-Au surface. The terrace width of the Si(553)-Au surface was widened uniformly by In adsorbates. The In-adsorbed Si(553)-Au surface was observed to have ×2 order along the wires with a much longer coherent length across the wires. Note that the room temperature (RT) ×2 order of the Si(553)-Au surface is due to the local ×2 charge density modulation caused mainly by defects. The In-induced reconstruction produces insulating atomic wires with similar electronic and atomic structures to those of the pristine Si(553)-Au surface.

The photoemission measurements were performed using a high-resolution electron analyzer (SES-100, Gamma Data) and a high-flux monochromatized HeI radiation (hν = 21.2 eV). The nominal energy and angular resolutions were better than 15 meV and 0.15°, respectively. A commercial variable-temperature scanning tunneling microscope (STM) (Omicron, Germany) was used. A Si(553) substrate (12.5° offcut from the [111] orientation) was cleaned thermally. A Si(553) surface with a regular atomic wire array was generated by depositing Au at 650 °C with a postannealing. Indium atoms were deposited using a heated graphite crucible.

Figure 1 shows the temperature dependence of the In-adsorbed Si(553)-Au surface. The low-energy-electron diffraction (LEED) pattern of the Si(553)-Au surface at RT is 1×2 (hereafter 1×2-Au), as shown in Fig. 1(a). The In adsorption of 1 ML (monolayer) on the 1×2-Au surface at RT changed the LEED pattern into a diffuse 1×1 phase. With increasing annealing temperature, the diffuse 1×1 phase changed gradually into a 1×2 phase which was optimized at 290 °C. A closer inspection revealed this In-induced 1×2 phase (hereafter 1×2-In) to have different long-range orders along and across the wires from the 1×2-Au phase. First, the period in k space across the wires was reduced from 0.42 to 0.35 Å⁻¹, as shown in Fig. 2(a). This suggests that the terrace width of the surface increases from 1.48 to 1.80 nm. The increased width agrees closely with a single unit cell of the lattice constant of the Si substrate across the wires, as shown in Figs. 3 and 4. Second, the ×2 LEED streaks of the 1×2-Au phase were sharpened into the spots in the 1×2-In phase. This suggests that the coherent length across the wires related to the ×2 period along the wires is enhanced. The change in long-range order indicates that the In adsorbates induce surface reconstruction. The LEED pattern and its line profiles across the wires at 550 °C became identical to those of the 1×2-Au surface, as
shown in Figs. 1(h) and 2(a). This suggests that the In adsorbates are desorbed at 550 °C and the 1×2-In surface changes into the 1×2-Au surface, which is also supported by the STM images and band structures, as described below.

The In-induced changes in the real space were visualized by STM [Figs. 4(a) and 4(b) for 1×2-Au and Figs. 3, 4(c), and 4(d) for 1×2-In]. The width of the single wire unit cell of the 1×2-Au surface is 1.48 nm and the single wire unit cell is composed of different atomic chains of step edge Si atoms, Si atoms within the terraces, and Au atoms.4,12,14 The Si atoms at the step edge have two broken bonds and the Au atoms substitute for Si surface atoms within the terrace.12 As detailed recently, the bright and dark chains, which were observed in both the filled-state and empty-state STM images [see Figs. 4(a) and 4(b)], correspond to the step edge and terrace atomic chains, respectively.15 Recent STM experiments showed that the terrace and step edge atomic chains of the 1×2-Au surface undergo charge density modulations from the RT to the low temperature (LT) period and from the RT×1 to the LT×3 period, respectively.4,14 At RT, a part of the terrace chains shows a local ×2 charge density

FIG. 1. The LEED pattern at a beam energy of 80 eV of the In-adsorbed Si(553)-Au surface at different annealing temperatures from RT to 550 °C. The 1×2 LEED pattern of the Si(553)-Au surface before In adsorption is shown in (a).

adsorbate-induced reconstruction of an array

The structural phase transition from the $1 \times 2$-Au to the $1 \times 2$-In surface was further studied by photoemission spectroscopy, as shown in Fig. 5. The band structure of the $1 \times 2$-Au surface at RT is composed of three fractional-filled 1D bands, two nearly half-filled bands ($S_1$ and $S_2$), and a single roughly third-filled band ($S_3$). The three 1D bands have dual electronic properties: the $S_1$ and $S_2$ bands are metallic but the $S_3$ band is semiconducting with a small energy gap of 40 meV at RT. The temperature-dependent band structures shown in Figs. 5(b)–5(g) were measured at near $k = 1.07$ Å$^{-1}$ of the $S_3$ band. The In adsorption at RT results in the disappearance of the $S_3$ band, which is partly due to the disordering of the surface observed by LEED. With increasing annealing temperature, the new energy band $S'_1$ evolves, which disperses approaching $k = 1.25$ Å$^{-1}$ at the Fermi level. The intensity of the $S'_1$ band was optimized at 290 °C. At higher temperatures, the $S'_1$ band fades away with the concomitant reappearance of the $S_1$ band. The temperature dependence of the $S'_1$ band is consistent with that of the $1 \times 2$-In LEED pattern, which proves that the $S'_1$ band originates from the $1 \times 2$-In surface.

Figure 6 shows the whole band structure along the wires of the $1 \times 2$-In surface prepared at the optimized temperature. Four energy bands were found to be located within the bulk band gap. Therefore, they are safely assigned as surface bands. Two of them ($S'_1$ and $S'_2$) are dispersive with bandwidths larger than 1.5 eV, while others ($S_3$ and $S'_3$) are very flat. The $S'_1$ and $S'_2$ bands with a band minimum at $k = 0.8$ Å$^{-1}$ approach $k = 1.40$ and 1.25 Å$^{-1}$, respectively, as they disperse to a low energy and are insulating with energy gaps of about 0.60 and 0.35 eV, respectively. The backfoldings of the $S'_1$ and $S'_2$ bands at the Brillouin zone boundary ($k = 1.23$ Å$^{-1}$) of the $\times 2$ period along the wires are not obvious but are expected to occur in order to satisfy the clear $\times 2$ period observed in LEED.

The band structure of the $1 \times 2$-In surface can be understood by two possible scenarios. The first is that the energy bands have completely different origins from those of the $1 \times 2$-Au surface due to the In-induced significant reconstruction. The second is that the In adsorption modifies the band structure of the $1 \times 2$-Au surface without dramatically changing its characteristics. We further consider how the In adsorbates can modify the electronic structure of the $1 \times 2$-Au surface. The energy dispersions of the $S'_1$ and $S'_3$ bands are quite similar to those of the $S_1/S_2$ and $S_3$ bands of...
were observed in both the filled-state and empty-state STM images, as shown in Fig. 4. Furthermore, the 1×2-In surface has nearly the same distance between the two atomic chains with that of the 1×2-Au surface. From the resemblances between the 1×2-In and 1×2-Au surfaces, it is more reasonable to interpret that the $S_1^/$ and $S_1'$ bands have similar origins to the $S_1^/$ and $S_1$ bands, respectively. The remaining question is how the band structures before and after the In-induced uniform terrace widening can be similar. The electronic and atomic structures of the Au-adsorbed stepped Si surfaces produce some indications. The number and band fillings of the dispersive 1D energy bands on the Au-adsorbed stepped Si surfaces depend on their step directions, where their terrace widths only change their band fillings slightly. Both the Si(335)-Au and Si(557)-Au surfaces have two half-filled bands and both the Si(553)-Au and Si(775)-Au surfaces have two half-filled bands and a single third-filled band. The uniform widening of the 1×2-Au terrace by a single lattice constant makes the Si(553) surface transit into the Si(332) surface, where terrace widening by two lattice constants produces the Si(775) surface. This can support that the 1×2-In surface has a similar band structure to the 1×2-Au surface and its surface bands originate from Si structures rather than from Au or In structures, as found on the 1×2-Au surface. On the other hand, the band fillings can also be changed by electron transfer from the In adsorbates passivating the 1×2-In surface. In any case, the atomic structure of the 1×2-In surface needs to be determined before a decisive assignment of the origins of the $S_1^/$ and $S_1'$ bands can be made.

In summary, the In-induced atomic and electronic phase transitions of the Si(553)-Au surface were studied using the combined LEED, STM, and potential energy surface experiments. The In adsorption results in the uniform terrace widening of the Si(553)-Au surface across the wires by 0.32 nm, which agrees closely with a single unit cell of the Si substrate. Furthermore, the In adsorbates drive ×2 order along the wires similar to the 1×2-Au surface but its coherent length across the wires is much longer than that of the 1×2-Au surface. The single wire unit cell of the 1×2-In surface with a width of 1.80 nm is composed of two different types of atomic wires located at the step edge and within the terrace, respectively, which is in close resemblance to the 1×2-Au surface. The step edge and terrace atomic chains produce two highly dispersive 1D bands with an energy gap of 0.35 and 0.6 eV, respectively. Therefore, In adsorbates drive the two metallic atomic chains on the 1×2-Au surface to change into the two insulating atomic chains with the same degree of anisotropy in the band structure.
